Synopsis

as Field Cycling MRI offers the possibility to explore new contrasts generated from NMR dispersion (NMRDJ profiles of tissue. Exploiting the dispersion properties of tissues may provide an additional biomarker of disea beper understanding of molecular mobility. Kidney tumors and healthy kidneys were analyzed among a cohort of twenty-seven mice to give insight into the potential of FFC-MRI for clinical applications. Here, we present aps performed around 1.5 T to show that the intrinsic dispersion of tumors measured in vivo differs from the one of healthy kidneys. maps perfo

Introduction

FaSt Field Cycling (FFC) enables to measure the evolution of the longitudinal relaxation rate R1as a function of magnetic field Bo, namely the nuclear magnetic resonance dispersion (NMRD) profile ^{1,5}. Combining FFC with MRI offers the possibility to perform localized innovative relaxometry measurements by accessing the NMRD profile *in vivo*, together with the usual characterization at fixed Bo. The ability of FFC-MRI to probe NMRD profiles in a time efficient manner as compared to multiple fields MRI systems maskes this technology of interest for biomedical applications. Here, we present *in viva* measurements of R1-dispersion maps performed at 1.5 T of healthy kidneys and kidney tumors in mice, providing insight into the potential of FFC-MRI to improve tumor characterization through a deeper understanding of molecular mobility.

Materials and Methods

Trenty-seven NSG (Nod Seld Gamma) mice were grafted on the left kidney with tissues issued from human kidney tumors. Tumor growth was monitored by ultrasound and FFC-MRI exams were planned when tumor size was at least half of the left kidney size (6 weeks up to S months); the right kidney was used as a control. The animals were anaesthetized with isoflurane. All experiments were approved by the local Ethics committee.

A resistive solenoidal 40-mm diameters Bo-Insert coli (Stelar s.r.L, Mede, Italy) connected to a current power amplifier was centered in a clinical 1.5 T MRI scanner. Field shifts as well as eddy currents compensation were controlled by a Tecmag pulse sequencer, synchronized to the MRI sequencer ^{5,7}. A 20-mm diameter RF surface coil was connected to the MRI scanner via an active T/R switch and placed on the back of the mice, on top of the kidneys.

Localization, T₁W and T₂W scans at 1.5 T were first performed (-30 min). For the dispersion measurements, inversion recovery (IR) images were obtained using a spin-echo sequence with the following parameters: TR/TE= 2 s /14 ms, FOV: 70x70 mm. matrix size: 144x144 pixels, pixel size: 0.5x0.5 mm, slice thickness: 2.5 mm. Three images were acquired at different evolution fields: 1.34 T, 1.5 T and 1.66 T with inversion time equal 540 ms after an initial adiabatic RF inversion pulse. Two other images were acquired at 1.5 T with different inversion times: 10 ms and 2 s. For the acquisitions at 1.34 and 1.66 T, a current intensity of 100 A enabled to reach fast{16 T/s} Bo field shifts of ±0.16 T during the inversion time. Data collection was always performed with Bo back at 1.5 T.

The IR images were fitted pixel-wise in the least square sense to the Bloch equation with a relaxation model including the equilibrium magnetization Mo and the relaxation rate R₁, as well as the slope of the dispersion profile dR₁/dBo at 1.5 T. A previous spectroscopic study showed that a linear approximation for the NMRD profile can be used ⁵. The protocol was initially validated on dispersive contrast agent solutions by comparison images to independent spectroscopic NMRD profile dent spectroscopic NMRD profile measurements.

The TI=540 ms inversion image at 1.ST provided a good T1contrast to identify the different kidney regions and the tumor (Fig.1). Uniform values for R1 and dispersion maps for the tumor (Fig.2) were obtained as well as differences between the medulia and the cortex (Fig.2). The tumor displayed lower R1 and dispersion than the medulia and the kidney (Fig.3). Considering the average values over the different regions of interest for all animals, a strong correlation (r=0.93) was observed between R1 and the dispersion.

Discussion/Conclusi on

Invivo messurements of R1-dispersion around 1.5 T have been performed in a kidney cancer model on 27 mice in a reproducible manner demonstrating stability of our unique FFC-MRI prototype. When averaged over a ROI, the slope of the NMRD profile could be used to differentiate tumors from healthy kidneys. The correlation of dispersion around 1.5 T with R1at 1.5 T augests that both parameters bears the similar information. If normalized by R1, it seems that correlation is reduced suggesting that dispersion properties may provide an additional biomarker. Sensitivity could be increased by producing higher field shifts or by using dynamic sequence instead of inversion recovery. Further *in vivo* analysis are needed to investigate the differences in R1-dispersion among various tumor types and healthy tissue and its potential benefit among existing MR parameters at fixed Ba field.
